Evidence-based practice tutorial – Randomised Controlled Trials: an introduction

A clinical trial is a method for comparing objectively, by a prospective study, the results of two or more therapeutic procedures. It aims to compare the response of a test group of patients receiving a new treatment with that of a control group who are receiving a standard treatment (or existing treatment) or occasionally a placebo or no treatment at all. The use of controls is important to substantiate claims of therapeutic efficacy for a procedure.

What is a randomised controlled trial?

Randomised controlled trials (RCTs) are one type of clinical trial design and are regarded by the scientific community to provide the ‘gold standard’ in terms of evidence when conducting primary research to study healthcare interventions. RCTs are commonly associated with pharmacological research and are less easily adaptable to the study of complex interventions such as osteopathy.

RCTs can use either a parallel design or a cross over design. The most common design is a parallel design. A parallel design is more likely to require larger numbers of patients than a cross-over design but is suitable for looking at both short and longer term conditions and is less likely to be affected by complications and patients dropping out than in cross-over designs. A parallel design uses two or more groups of patients who are studied concurrently; each group receives one of the possible treatment interventions being studied. The parallel design can be demonstrated:

<table>
<thead>
<tr>
<th>Patient Group A</th>
<th>Treatment 1</th>
</tr>
</thead>
<tbody>
<tr>
<td>Patient Group B</td>
<td>Treatment 2</td>
</tr>
</tbody>
</table>
Parallel Study Design

Why are randomised controlled trials needed?

If a simple trial is conducted with no comparison group, the outcome observed cannot be attributed to the treatment intervention with any great degree of confidence.

When non-randomised controlled trials are used, they may be difficult to interpret since not all of the subjects have the same chance to receive the treatment intervention; the control and intervention group may differ in terms of age, sex, height, weight or other features which will be relevant to the final outcome of the study. Random allocation attempts to make the intervention groups as similar as possible in terms of these factors. Random allocation is achieved using tables of random numbers or computer generated random numbers e.g. using sites such as www.random.org.

Concern inevitably arises over the ethical issues of assigning patients at random to an untreated group when a test treatment is believed to be advantageous. Randomisation is essential to avoid bias in assigning individual patients to test or control groups. Hence the randomised controlled trial is now regarded as the essential tool for assessing clinical efficacy.

Randomisation is one of two main strategies to minimise bias in clinical trials; the double blind technique is another method to minimise bias. However, in small groups of patients, groups can still end up being poorly matched and a compromise solution is to split the series into blocks of e.g. eight patients within each block consisting of four patients for group A and four for group B. Another difficulty with simple randomisation is that the two groups can turn out to be ill-matched with respect to a variety of characteristics including age, sex or disease severity. The chance of mismatch decreases as the size of the series increases. In small scale trials stratified randomisation is used to avoid this difficulty. The subjects might be divided into age categories and random allocation to each group can be used within each category.
How is an RCT conducted?

Identification of treatment intervention
↓
Selection of study population
↓
Obtain ethical approval
↓
Provide information concerning the treatment intervention and risks
↓
Obtain informed consent
↓
Randomise members of study population to control or treatment intervention groups
Provide the treatment intervention employing blinding/masking to either study subject OR therapist (single blind) or study subject AND therapist (double blind)
↓
Measure outcomes at time intervals as defined in the study protocol using a blinded-masked/independent assessor
↓
Follow up any losses from the study population
↓
Analysis of all outcomes using a blinded-masked/independent analyst
↓
Write up findings
↓
Dissemination of findings to suitable audiences e.g. conferences, patient groups, peer reviewed journals
**Terminology**

**Blinding/masking:** This is the method of concealing the allocation of a sample of people, for example to an experimental group or a control group during the research process. This concealment can be from the individuals involved in the research process *(single blind)* or concealment from both researchers and research participants *(double blind)*. The term masking is now commonly used to replace the use of the term blinding.

**Consent:** The process whereby a patient freely agrees without coercion or pressure to be involved in a research project. Consent can only be given when a full explanation of the process, potential risks and rewards have been fully explained to the patient and presented to them as a formal document in a form in which they are able to understand (translated into another language, Braille or auditory version). Written consent is required from all participants in a research study. If this can not be given by the patient involved, it can be given by a legal representative, guardian or other responsible appointed adult at the participant’s behest.

**Control Group:** The group in an experimental process that is not exposed to an intervention/treatment. This group can then be compared to the experimental group receiving treatment to study the effects of the intervention.

Further information concerning jargon in research groups can be found at [www.ncor.org.uk](http://www.ncor.org.uk) in the *evidence-based practice tutorials* found in the section headed *Learning Online*. The randomized controlled trial is only one of a number of research designs. Further information concerning other research designs will be presented in future evidence-based practice tutorials.
